1. INTRODUCTION

This report describes in details the radiation scheme which, since 2 May 1989, is part of the package of parametrizations for the physical processes in the ECMWF forecast model (ECMWF Research Manual 3). This radiation package calculates the heating/cooling rate due to absorption-emission of longwave radiation and reflection, scattering and absorption of solar radiation by the earth's atmosphere and surfaces. Outline of the code, in the format of Stephens's (1984) paper, is given in Table 1. The longwave and shortwave radiation parts of the scheme are described in details in sections 2 and 3, respectively.

Timing: 8 ms for a column computation for a 19-level model on a CRAY XMP-48
2. **LONGWAVE RADIATION**

The rate of atmospheric cooling by emission-absorption of longwave radiation is

\[
\frac{dT}{dt} = \frac{g}{C_p} \frac{dF}{dp}
\]  \hspace{1cm} (2.1)

where \(F\) is the net total longwave flux.

Assuming a non-scattering atmosphere in local thermodynamic equilibrium, \(F\) is given

\[
F = \mu \int_{-1}^{+1} \int_{0}^{\infty} \left[ L_{\nu}(p_s, \mu) t_{\nu}(p_s, p, \mu) + \int_{p_s}^{0} L_{\nu}(p', \mu) \, dp' \right] \, d\nu \, d\mu
\]  \hspace{1cm} (2.2)

where \(L_{\nu}(p, \mu)\) is the monochromatic radiance of wavenumber \(\nu\) at level \(p\) propagating in a direction such as \(\mu\) is the cosine of the angle that this direction makes with the vertical, and \(t_{\nu}(p, p', \mu)\) is the monochromatic transmission through a layer whose limits are at \(p\) and \(p'\) seen under the same angle \(\theta\).

After separating the upward and downward components, and integrating by parts, we obtain the radiation transfer equation as it is actually estimated in the radiation code

\[
F_{\nu}^+(p) = \left[ B_{\nu}(T_S) - B_{\nu}(T_0^+) \right] t_{\nu}(p_s, p; r) + B_{\nu}(T_p) + \int_{p_s}^{p} t_{\nu}(p, p'; r) \, dB_{\nu}
\]  \hspace{1cm} (2.3)
\[ F_{\nu}^{-}(p) = \left[ B_{\nu}(T_{T}) - B_{\nu}(T_{\infty}) \right] t_{\nu}(p,0;r) + B_{\nu}(T_{p}) \]

\[ + \int_{p}^{0} t_{\nu}(p',p;r) \, dB_{\nu} \]

where, taking benefit of the isotropic nature of the longwave radiation, the radiance \( L_{\nu} \) of (2.2) is replaced by Planck function \( B_{\nu}(T) \) in unit of flux, \( \text{Wm}^{-2} \) (hereafter \( B_{\nu} \) always includes the \( \pi \) factor). \( T_{S} \) is the surface temperature, \( T_{0+} \) that of the air just above the surface, \( T_{p} \) is the temperature at level of pressure \( p \), \( T_{t} \) that at the top of the atmospheric model. The transmission \( t_{\nu} \) is evaluated as the radianse transmission in a direction \( \theta \) to the vertical such that \( r = \sec \theta \) is the diffusivity factor (Elsasser, 1942). Such an approximation for the integration over the angle is usual in radiative transfer calculations, and tests on the validity of this approximation have been presented by Rodgers and Walshaw (1966) among others. The use of the diffusivity factor gives cooling rates within 2% of those obtained with a 4-point Gaussian quadrature.

2.1 Vertical integration

The integrals in (2.3) are evaluated numerically, after discretization over the vertical grid, considering the atmosphere as a pile of homogeneous layers. As the cooling rate is strongly dependent on local conditions of temperature and pressure, and energy is mainly exchanged with the layers adjacent to the level where fluxes are calculated, the contribution of the distant layers is simply computed using a trapezoidal rule integration, but the contribution of the adjacent layers is evaluated with a 2-point Gaussian quadrature, thus

\[ \int_{p_s}^{p_1} t_{\nu}(p,p';r) = \sum_{l=1}^{2} dB_{\nu}(l) \, w_{l} \, t_{\nu}(p_{l},p_{l};r) \]

\[ + \frac{1}{2^1-2} \sum_{j=1}^{1-2} dB_{\nu}(j) \left[ t_{\nu}(p_{1},p_{j},r) + t_{\nu}(p_{1},p_{j-1},r) \right] \]

(2.4)
where \( p_1 \) and \( w_1 \) are the pressure corresponding to the gaussian root and the gaussian weight, respectively. \( dB_p(j) \) and \( dB_v(1) \) are the Planck function gradients calculated between two interfaces, and between mid-layer and interface, respectively.

2.2 Spectral integration

The integration over wavenumber \( \nu \) is performed using a band emissivity method, as first discussed by Rodgers (1967). The longwave spectrum is divided into six spectral regions:

1. \( 0 \) - \( 350 \) cm\(^{-1} \) + \( 1450 \) - \( 1880 \) cm\(^{-1} \)
2. \( 500 \) - \( 800 \) cm\(^{-1} \)
3. \( 800 \) - \( 970 \) cm\(^{-1} \) + \( 1110 \) - \( 1250 \) cm\(^{-1} \)
4. \( 970 \) - \( 1110 \) cm\(^{-1} \)
5. \( 350 \) - \( 500 \) cm\(^{-1} \)
6. \( 1250 \) - \( 1450 \) cm\(^{-1} \) + \( 1880 \) - \( 2820 \) cm\(^{-1} \)

corresponding to the centers of the rotation and vibration-rotation bands of \( \text{H}_2\text{O} \), the 15 micron band of \( \text{CO}_2 \), the atmospheric window, the 9.6 micron band of \( \text{O}_3 \), the 25 micron "window" region, and the wings of the vibration-rotation band of \( \text{H}_2\text{O} \), respectively. Over these spectral regions, band fluxes are evaluated with the help of band transmissivities precalculated from the narrow-band model of Morcrette and Fouquart (1985) -- See Appendix of Morcrette et al. (1986) for details --.

Integration of (2.3) over wavenumber \( \nu \) within the \( k \)-th spectral region gives the upward and downward fluxes as

\[
F_k^+(p) = [B_k(T_s) - B_k(T_{0+})] t_k (ru(p_s,p), T_u(p_s,p)) + B_k(T_p) \\
+ \int_{p_s}^{p} t_d B_k (ru(p,p'), T_u(p,p')) dB_k 
\]

(2.5a)
\[ F_k^-(p) = \left[ B_k(T_0^0) - B_k(T_\infty) \right] t_{B_k}(ru(p,0), T_u(p,0)) - B_k(T_p) \]

\[ - \int_0^0 t_{dB_k}(ru(p',p), T_u(p',p)) dB_k \]

(2.5b)

The formulation accounts for the different temperature dependences involved in atmospheric flux calculations, namely that on \( T_p \), the temperature at the level where fluxes are calculated, and that on \( T_u \), the temperature that governs the transmission through the temperature dependence of the intensities and half-widths of the lines absorbing in the concerned spectral region. The band transmissivities are non-isothermal accounting for the temperature dependence that arises from the wavenumber integration of the product of the monochromatic absorption and the Planck function. Two normalized band transmissivities are used for each absorber in a given spectral region: the first one for calculating the first r.h.s. term in (2.3), involving the boundaries; it corresponds to the weighted average of the transmission function by the Planck function

\[
t_B(\bar{u}p, T_p, T_u) = \frac{\int_{\nu_1}^{\nu_2} B_\nu(T_p) t_\nu(\bar{u}p, T_u) d\nu}{\int_{\nu_1}^{\nu_2} B_\nu(T_p) d\nu} \tag{2.6a}
\]

the second one for calculating the integral terms in (2.3) is the weighted average of the transmission function by the derivative of the Planck function

\[
t_{dB}(\bar{u}p, T_p, T_u) = \frac{\int_{\nu_1}^{\nu_2} dB_\nu(T_p)/dT \ t_\nu(\bar{u}p, T_u) d\nu}{\int_{\nu_1}^{\nu_2} dB_\nu(T_p)/dT d\nu} \tag{2.6b}
\]

where \( \bar{u}p \) is the pressure weighted amount of absorber.
In the scheme, the actual dependence on $T_p$ is carried out explicitly in the Planck functions integrated over the spectral regions. Although normalized relative to $B(T_p)$ (or $dB(T_p)/dT$), the transmissivities still depend on $T_u$, both through Wien's displacement of the maximum of the Planck function with temperature and through the temperature dependence of the absorption coefficients. For computational efficiency, the transmissivities have been developed into Padé approximants

$$t(\tilde{u}p, T_u) = \frac{\sum_{i=0}^{2} C_i \ u_{\text{eff}}^{i/2}}{\sum_{j=0}^{2} D_j \ u_{\text{eff}}^{j/2}}$$ (2.7)

where $u_{\text{eff}} = r \ \tilde{u}p \ f(T_u, \tilde{u}p)$ is an effective amount of absorber which incorporates the diffusivity factor $r$, the weighting of the absorber amount by pressure, $\tilde{u}p$, and the temperature dependence of the absorption coefficients, with

$$f(T_u, \tilde{u}p) = \exp \left[ a(\tilde{u}p) (T_u - 250) + b(\tilde{u}p) (T_u - 250)^2 \right]$$ (2.8)

The temperature dependence due to Wien's law is incorporated although there is no explicit variation of the coefficients $C_i$ and $D_j$ with temperature. These coefficients have been computed for temperatures between 187.5 and 312.5 K with a 12.5 K step, and transmissivities corresponding to the reference temperature the closest to the pressure weighted temperature $T_u$ are actually used in the scheme.

2.3 Incorporation of the effects of clouds

The incorporation of the effects of clouds on the longwave fluxes follows the treatment discussed by Washington and Williamson (1977). Whatever the state of cloudiness of the atmosphere, the scheme starts by calculating the fluxes
corresponding to a clear-sky atmosphere and stores the terms of the energy exchange between the different levels (the integrals in (2.3)). Let $F^+_0(1)$ and $F^-_0(1)$ be the upward and downward clear-sky fluxes. For any cloud layer actually present in the atmosphere, the scheme then evaluates the fluxes assuming a unique overcast cloud of unity emissivity. Let $F^+_n(1)$ and $F^-_n(1)$ the upward and downward fluxes when such a cloud is present in the n-th layer of the atmosphere. Downward fluxes above the cloud and upward fluxes below it have kept their clear-sky values

\begin{align}
F^+_n(1) &= F^+_0(1) \quad \text{for } i \leq n \\
F^-_n(1) &= F^-_0(1) \quad \text{for } i > n
\end{align}

(2.9)

Upward fluxes above the cloud ($F^+_n(k)$ for $k \geq n+1$) and downward fluxes below it ($F^-_n(k)$ for $k < n$) can be expressed with expressions similar to (2.3) provided the boundary terms are now replaced by terms corresponding to possible temperature discontinuities between the cloud and the surrounding air.

\begin{align}
F^+_n(k) &= [F^+_\text{cld} - B(n+1)] \ t(p_k,p_{n+1};r) + B(k) + \int_{p_{n+1}}^{p_k} t(p_k,p';r) \ dB \\
F^-_n(k) &= [F^-\text{cld} - B(n)] \ t(p_k,p_n ; r) + B(k) + \int_{p_k}^{p_n} t(p',p_k;r) \ dB
\end{align}

(2.10)

where $B(i)$ is now the total Planck function (integrated over the whole longwave spectrum) at level $i$, and $F^\text{cld}_+$ and $F^\text{cld}_-$ are the fluxes at the upper and lower boundaries of the cloud. Terms under the integrals correspond to exchange of energy between layers in clear-sky atmosphere and have already been computed in the first step of the calculations. This step is repeated for all cloudy layers. The fluxes for the actual atmosphere (with semi-transparent, fractional and/or multi-layered clouds) are derived from a linear combination of the fluxes calculated at the previous steps with some cloud overlap assumption in the case of clouds present in several layers. Let
N be the index of the layer containing the highest cloud, \( C_1 \) the fractional cloud cover in layer \( i \), with \( C_0 = 1 \) for the upward flux at the surface, and with \( C_{N+1} = 1 \) and \( F^-_{N+1} = F_0^- \) to have the right boundary condition for downward fluxes above the highest cloud. The cloudy upward (\( F^+ \)) and downward (\( F^- \)) fluxes are obtained as

\[
F^+(i) = F_0^+ (1) \quad \text{for } i=1
\]

\[
F^+(i) = C_{i-1} F^+_{i-1} (1) + \sum_{n=0}^{i-2} C_n F^+_{n} (1) \prod_{l=n+1}^{i-1} (1 - C_l) \quad \text{for } 2 \leq i \leq N+1
\]

\[
F^+(i) = C_N F^+_{N} (1) + \sum_{n=0}^{N-1} C_n F^+_{n} (1) \prod_{l=n+1}^{N} (1 - C_l) \quad \text{for } i \geq N+2
\]

(2.11)

In case of semi-transparent clouds, the fractional cloudiness entering the calculations is an effective cloud cover equal to the product of the emissivity by the horizontal coverage of the cloud layer, with the emissivity related to the cloud liquid water amount by

\[
\varepsilon_{cid} = 1 - \exp \left( - K_{\text{abs}} \frac{u_{\text{LWP}}}{L} \right)
\]

(2.12)

where \( K_{\text{abs}} \) is the liquid water mass absorption coefficient set to 158 m\(^2\)kg\(^{-1}\) according to Stephens (1978, 1979).
3. SHORTWAVE RADIATION

The rate of atmospheric heating by absorption and scattering of shortwave radiation is

\[
\frac{dT}{dt} = \frac{g}{C_p} \frac{dF}{dp} \tag{3.1}
\]

where \(F\) is the net total shortwave flux

\[
F(\delta) = \int_{0}^{\infty} d\nu \int_{0}^{2\pi} d\phi \int_{-1}^{+1} \mu L_v(\delta, \mu, \phi) \, d\mu \, d\phi \tag{3.2}
\]

\(L_v\) is the diffuse radiance at wavenumber \(v\), in a direction given by \(\phi\) the azimuth angle and \(\mu = \cos \theta\), with \(\theta\) the zenith angle. In (3.2), we assume a plane parallel atmosphere, and the vertical coordinate is the optical depth \(\delta\) a convenient variable when the energy source is outside the medium

\[
\delta(p) = \int_{0}^{p} \beta^\text{ext}(p) \, dp \tag{3.3}
\]

\(\beta^\text{ext}(p)\) is the extinction coefficient equal to the sum of the scattering coefficient \(\beta^\text{sca}\), of the aerosol or cloud particle absorption coefficient \(\beta^\text{abs}\), and of the purely molecular absorption coefficient \(k_v\). The diffuse radiance \(L_v\) is governed by the radiation transfer equation

\[
\mu \frac{dL_v(\delta, \mu, \phi)}{d\delta} = L_v(\delta, \mu, \phi) - \frac{\bar{\omega}_v(\delta)}{4} P_v(\delta, \mu, \phi, \mu^o, \phi^o) E^o_v e^{-\delta} \mu^o
\]

\[
- \frac{\bar{\omega}_v(\delta)}{4} \int_{0}^{2\pi} \int_{-1}^{+1} P_v(\delta, \mu, \phi, \mu', \phi') L_v(\delta, \mu', \phi') \, d\mu' \, d\phi' \tag{3.4}
\]

\(E^o_v\) is the incident solar irradiance in the direction \(\mu^o = \cos \theta^o\), \(\bar{\omega}_v\) is the single scattering albedo (\(= \beta^\text{sca}_v / K_v\)) and \(P(\delta, \mu, \phi, \mu', \phi')\) is the scattering phase function which defines the probability that radiation coming from
direction \((μ', φ')\) is scattered in direction \((μ, φ)\). The shortwave part of the scheme, originally developed by Fouquart and Bonnel (1980) solves the radiation transfer equation and integrates the fluxes over the whole shortwave spectrum between 0.2 and 4 microns. Upward and downward fluxes are obtained from the reflectances and transmittances of the layers, and the photon path distribution method allows to separate the parametrization of the scattering processes from that of the molecular absorption.

3.1 Spectral integration

Solar radiation is attenuated by absorbing gases, mainly water vapor, carbon dioxide, oxygen and ozone, and scattered by molecules (Rayleigh scattering), aerosols and cloud particles. Since scattering and molecular absorption occur simultaneously, the exact amount of absorber along the photon path length is unknown, and band models of the transmission function cannot be used directly as in longwave radiation transfer (see 2.1) The approach of the photon path distribution method is to calculate the probability \(p(U)\) d\(U\) that a photon contributing to the flux \(F_c\) in the conservative case (i.e., no absorption, \(\bar{ω}_ν = 1, k_ν = 0\)) has encountered an absorber amount between \(U\) and \(U + dU\). With this distribution, the radiative flux at wavenumber \(ν\) is related to \(F_c\) by

\[
F_ν = F_c \int_0^∞ p(U) \exp(-k_ν U) dU
\]

(3.5)

and the flux averaged over the spectral interval \(Δν\) can then be calculated with the help of any band model of the transmission function \(t_{Δν}\)

\[
F = \frac{1}{Δν} \int_Δν F_ν dν = F_c \int_0^∞ p(U) t_{Δν}(U) dν
\]

(3.6)

To find the distribution function \(p(U)\), the scattering problem is solved first, by any method, for a set of arbitrarily fixed absorption coefficients \(k_1\), thus giving a set of simulated fluxes \(F_{k_1}\). An inverse Laplace transform is then performed on (3.5) to get \(p(U)\) (Fouquart, 1974). The main advantage of
the method is that the actual distribution \( p(U) \) is smooth enough that (3.5) gives accurate results even if \( p(U) \) itself is not known accurately. In fact, \( p(U) \) needs not be calculated explicitly as the spectrally integrated fluxes are

\[
F = F_c t_{\Delta \nu} \langle U \rangle \quad \text{in the limiting case of weak absorption} \tag{3.7}
\]

\[
F = F_c t_{\Delta \nu}^{1/2} \langle U \rangle \quad \text{in the limiting case of strong absorption}
\]

where \( \langle U \rangle = \int_0^\infty p(U) \, U \, dU \) and \( \langle U \rangle^{1/2} = \int_0^\infty p(U) \, U^{1/2} \, dU \).

The atmospheric absorption in the water vapor bands is generally strong, and the scheme determines an effective absorber amount \( U_e \) between \( \langle U \rangle \) and \( \langle U \rangle^{1/2} \) derived from

\[
U_e = \ln \left( \frac{F_e}{F_c} \right) / k_e \tag{3.8}
\]

where \( k_e \) is an absorption coefficient chosen to approximate the spectrally averaged transmission of the clear-sky atmosphere

\[
k_e = \frac{1}{U_{\text{tot}} / \mu_o} \ln \left( \frac{t_{\Delta \nu}(U_{\text{tot}} / \mu_o)}{\mu_o} \right) \tag{3.9}
\]

where \( U_{\text{tot}} \) is the total amount of absorber in a vertical column and \( \mu_o = \cos \theta_o \). Once the effective absorber amounts of \( H_2O \) and uniformly mixed gases are found, the transmission functions are computed using Padé approximants

\[
t_{\Delta \nu}(U) = \sum_{i=0}^{N} \frac{a_i}{b_j} U^{i-1-1} \tag{3.10}
\]
Absorption by ozone is also taken into account, but since ozone is located at low pressure levels for which molecular scattering is small and Mie scattering is negligible, interactions between scattering processes and ozone absorption are neglected. Transmission through ozone is computed using (3.10) where $U_{O_3}$, the amount of ozone is

$$U_{O_3}^d = M \int_p^0 dU_{O_3}$$

for the downward transmission of the direct solar beam,

$$U_{O_3}^u = r \int_p^b dU_{O_3} + U_{O_3}^d(p_s)$$

for the upward transmission of the diffuse radiation;

$r = 1.66$ is the diffusivity factor (see 3.), and $M$ is the magnification factor (Rodgers, 1967) used instead of $\mu_o$ to account for the sphericity of the atmosphere at very small solar elevations

$$M = \frac{35}{\sqrt{1224 \mu_o^2 + 1}}$$

(3.11)

To perform the spectral integration, it is convenient to discretize the solar spectral interval into subintervals in which the surface reflectance can be considered as constant. Since the main cause of the important spectral variation of the surface albedo is the sharp increase in the reflectivity of the vegetation in the near infrared, and since water vapor does not absorb below 0.68 $\mu$m, the shortwave scheme considers two spectral intervals, one for the visible ($0.2 - 0.68$ $\mu$m), one for the near infrared ($0.68 - 4.0$ $\mu$m) parts of the solar spectrum. This cut-off at 0.68 $\mu$m also makes the scheme more computationally efficient, inasmuch as the interactions between gaseous absorption (by water vapor and uniformly mixed gases) and scattering processes are accounted for only in the near-infrared interval.
3.2 Vertical integration

Contrarily to the scheme of Geleyn and Hollingsworth (1979), the fluxes are not obtained through the solution of a system of linear equations in a matrix form. Rather, assuming an atmosphere divided into \( N \) homogeneous layers, the upward and downward fluxes at a given layer interface \( j \) are given by

\[
F^-(j) = F_0 \prod_{k=j}^{N} T_b(k) \\
F^+(j) = F^-(j) R_t(j-1)
\]

(3.12)

where \( R_t(j) \) and \( T_b(j) \) are the reflectance at the top and the transmittance at the bottom of the \( j \)-th layer. Computations of \( R_t \)'s start at the surface and work upward, whereas those of \( T_b \)'s start at the top of the atmosphere and work downward. \( R_t \) and \( T_b \) account for the presence of cloud in the layer

\[
R_t = C R_{\text{cdy}} + (1 - C) R_{\text{clr}} \\
T_b = C T_{\text{cdy}} + (1 - C) T_{\text{clr}}
\]

(3.13)

clr and cdy respectively refer to the clear-sky and cloudy fractions of the layer, and \( C \) is the cloud fractional coverage.

3.2.1 Cloudy fraction of the layers

\( R_{t_{\text{cdy}}} \) and \( T_{b_{\text{cdy}}} \) are the reflectance at the top and transmittance at the bottom of the cloudy fraction of the layer calculated with the Delta-Eddington Approximation. Given \( \delta_c \), \( \delta_a \), and \( \delta_g \), the optical thicknesses for the cloud, the aerosol and the molecular absorption (= \( k_c U \)), and \( g_c \) and \( g_a \) the cloud and aerosol asymmetry factors, \( R_{t_{\text{cdy}}} \) and \( T_{b_{\text{cdy}}} \) are calculated as functions of the total optical thickness of the layer

\[
\delta = \delta_c + \delta_a + \delta_g
\]
of the total single scattering albedo

\[ \omega^* = \frac{\delta_c + \delta_a}{\delta_c + \delta_a + \delta_g} \]  \hspace{1cm} (3.14)

of the total asymmetry factor

\[ g^* = \frac{\delta_c}{\delta_c + \delta_a} g_c + \frac{\delta_a}{\delta_c + \delta_a} g_a \]

of the reflectance \( R_\lambda \) of the underlying medium (surface or layers below the \( j \)-th interface), and of an effective solar zenith angle \( u_e(j) \) which accounts for the decrease of the direct solar beam and the corresponding increase of the diffuse part of the downward radiation by the upper scattering layers.

\[ u_e(j) = \left[ \frac{1 - C_{al}^1(j)}{\mu + r C_{al}^1(j)} \right]^{-1} \]  \hspace{1cm} (3.15)

with

\[ C_{al}^1(j) = 1 - \prod_{i=j+1}^{N} \left( 1 - C(1) E(i) \right) \]

and

\[ E(i) = 1 - \exp \left[ - \frac{\left( 1 - \omega_c(1) g_c(1)^2 \right) \delta_c(1)}{\mu} \right] \]  \hspace{1cm} (3.16)

\( \delta_c(1), \omega_c(1) \) and \( g_c(1) \) are the optical thickness, single scattering albedo and asymmetry factor of the cloud in the \( i \)-th layer, and \( r \) is the diffusivity factor. The scheme follows the Eddington Approximation, first proposed by Shettle and Weinman (1970), then modified by Joseph et al. (1976) to account more accurately for the large fraction of radiation directly transmitted in
the forward scattering peak in case of highly asymmetric phase functions. Eddington's approximation assumes that, in a scattering medium of optical thickness $t_0^*$, of single scattering albedo $w$, and of asymmetry factor $g$, the radiance $L$ entering (3.4) can be written as

$$ L(\delta, \mu) = L_0(\delta) + \mu L_1(\delta) \quad (3.17) $$

In that case, when the phase function is expanded as a series of associated Legendre functions, all terms of order greater than one vanish when (3.4) is integrated over $\mu$ and $\phi$. The phase function is therefore given by

$$ P(\theta) = 1 + \beta_1(\theta) \cos \theta $$

where $\theta$ is the angle between incident and scattered radiances. The integral in (3.4) thus becomes

$$ \int_0^{2\pi} \int_{-1}^{+1} P(\mu, \phi, \mu', \phi') L(\mu', \phi') \, d\mu' d\phi' = 4\pi \left( L_0 + n L_1 \right) \quad (3.18) $$

where

$$ g = \frac{\beta_1}{3} = \frac{1}{2} \int_{-1}^{+1} P(\theta) \cos \theta \, d(\cos \theta) $$

is the asymmetry factor.

Using (3.18) in (3.4) after integrating over $\mu$ and dividing by $2\pi$, we get

$$ \mu \frac{d(L_0 + \mu L_1)}{d\delta} = - (L_0 + \mu L_1) + \omega (L_0 + g \mu L_1) $$

$$ + \frac{1}{4} \omega F_0 \exp(-\delta/\mu_0) (1 + 3g \mu_0 \mu) \quad (3.19) $$
We obtain a pair of equations for $L_0$ and $L_1$ by integrating (3.19) over $\mu$

$$\frac{d L_0}{d \delta} = -3 (1 - \omega) L_0 + \frac{3}{4} \omega F_0 \exp\left(-\delta / \mu_0\right)$$  \hspace{1cm} (3.20)$$

$$\frac{d L_1}{d \delta} = - (1 - \omega g) L_1 + \frac{3}{4} \omega g \mu_0 F_0 \exp\left(-\delta / \mu_0\right)$$  \hspace{1cm} (3.21)$$

For the cloudy layer assumed non-conservative ($\omega < 1$), the solutions to (3.20) and (3.21), for $0 \leq \delta \leq \delta^*$, are

$$L_0(\delta) = C_1 \exp(-k\delta) + C_2 \exp(+k\delta) - \alpha \exp(-\delta/\mu_0)$$  \hspace{1cm} (3.22)$$

$$L_1(\delta) = p \left( C_1 \exp(-k\delta) - C_2 \exp(+k\delta) \right) - \beta \exp(-\delta/\mu_0)$$

where

$$k = \left[ 3 (1-\omega) (1-\omega g) \right]^{1/2}$$

$$p = \left[ 3 (1-\omega)/(1-\omega g) \right]^{1/2}$$

$$\alpha = 3 \omega F_0 \mu_0^2 \left[ 1 + g (1-\omega) \right] / 4 \left( 1 - k^2 \mu_0^2 \right)$$

$$\beta = 3 \omega F_0 \mu_0 \left[ 1 + 3g (1-\omega) \mu_0^2 \right] / 4 \left( 1 - k^2 \mu_0^2 \right)$$

The two boundary conditions allow to solve the system for $C_1$ and $C_2$; the downward directed diffuse flux at the top of the layer is zero, i.e.,

$$F^-(0) = \left[ L_0(0) + \frac{2}{3} L_1(0) \right] = 0$$

17
which translates into

\[(1 + 2p/3) C_1 + (1 - 2p/3) C_2 = \alpha + 2\beta/3 \quad (3.23)\]

the upward directed flux at the bottom of the layer is equal to the product of
the downward directed diffuse and direct fluxes and the corresponding diffuse
and direct reflectances \((R_d, R_\perp)\), respectively, of the underlying medium.

\[
F^*(\delta^*) = \left[ L_0(\delta^*) - \frac{2}{3} L_1(\delta^*) \right]
= R_\perp[L_0(\delta^*) + \frac{2}{3} L_1(\delta^*)] + R_d \mu_0 F_0 \exp(-\delta^*/\mu_0)
\]

which translates into

\[
(1 - R_\perp - 2 (1 + R_\perp) p / 3) C_1 \exp(-k \delta^*)
+ (1 - R_\perp + 2 (1 + R_\perp) p / 3) C_2 \exp(+k \delta^*) \quad (3.24)
= ( (1 - R_\perp) \alpha - 2 (1 + R_\perp) \beta / 3 + R_d \mu_0 F_0 ) \exp(-\delta^*/\mu_0)
\]

In the Delta-Eddington approximation, the phase function is approximated by a
Dirac delta function forward scatter peak and a two-term expansion of the
phase function.

\[
P(\theta) = 2 f (1 - \cos \theta) + (1 - f) (1 + 3g' \cos \theta)
\]

where \(f\) is the fractional scattering into the forward peak and \(g'\) the
asymmetry factor of the truncated phase function. As shown by Joseph et al.
(1976), these parameters are

\[
f = g^2 \quad (3.25)

g' = g / (1+g)
\]
The solution of the Eddington's equations remains the same provided that the total optical thickness, single scattering albedo and asymmetry factor entering (3.19)-(3.24) take their transformed values

$$
\delta^* = (1 - \omega f) \delta^*
$$

$$
\omega' = \frac{(1 - f) \omega}{1 - \omega f}
$$

Practically, the optical thickness, single scattering albedo, asymmetry factor, and solar zenith angle entering (3.23)-(3.26) are $\delta^*$, $\omega^*$, $g^*$ and $u_e$ defined in (3.14) and (3.15).

3.2.2 Clear-sky fraction of the layers

In the clear-sky fraction of the layers, the shortwave scheme accounts for scattering and absorption by molecules and aerosols. As the optical thickness for both Rayleigh and aerosol scattering is small, $R_{c1r}(j-1)$ and $T_{c1r}(j)$, the reflectance at the top and transmittance at the bottom of the j-th layer can be calculated using respectively a first and a second-order expansion of the analytical solutions of the two-stream equations similar to that of Coakley and Chylek (1975). For Rayleigh scattering, the optical thickness, single scattering albedo and asymmetry factor are respectively $\delta_R$, $\omega_R = 1$, and $g_R = 0$, so that

$$
R_R = \frac{\delta_R}{(2\mu + \delta_R)}
$$

$$
T_R = \frac{2\mu}{(2\mu + \delta_R)}
$$

The optical thickness $\delta_R$ of an atmospheric layer is simply

$$
\delta_R = \delta^* \frac{p(j) - p(j-1)}{p_{surf}}
$$
where \( \delta^*_R \) is the Rayleigh optical thickness of the whole atmosphere parametrized as a function of the solar zenith angle (Deschamps et al., 1983)

\[
\delta^*_R = \sum_{i=0}^{5} a_i \mu_0^{i-1}
\]

For aerosol scattering and absorption, the optical thickness, single scattering albedo and asymmetry factor are respectively \( \delta_a \), \( \omega_a \) (with \( 1 - \omega_a \ll 1 \)) and \( g_a \), so that

\[
den = 1 + \left( 1 - \omega_a + \text{back}(\mu_e) \omega_a \right) \delta_a / \mu_e \\
+ \left( 1 - \omega_a \right) \left( 1 - \omega_a + 2 \text{back}(\mu_e) \omega_a \right) \delta_a^2 / \mu_a^2
\]

\[
R(\mu_e) = \frac{\text{back}(\mu_e) \omega_a \delta_a / \mu_e}{den}
\]

\[
T(\mu_e) = \frac{1}{den}
\]

(3.28)

where \( \text{back}(\mu_e) = \left( 2 - 3 \mu_e g_a \right) / 4 \) is the backscattering factor.

Practically, \( R_{\text{clr}} \) and \( T_{\text{clr}} \) are computed using (3.28) and the combined effect of aerosol and Rayleigh scattering comes from using modified parameters corresponding to the addition of the two scatterers with provision for the highly asymmetric aerosol phase function through a Delta-approximation of the forward scattering peak (as in (3.25)-(3.26))

\[
\delta^* = \delta_R + \delta_a \left( 1 - \omega_a g_a^2 \right)
\]

\[
g^* = \frac{g_a}{1 + g_a} \frac{\delta_a}{\delta_R + \delta_a}
\]

(3.29)
\[ \omega^+ = \frac{\delta_R}{\delta_R + \delta_a} \omega_R + \frac{\delta_a}{\delta_R + \delta_a} \frac{\omega_a (1 - g_a^2)}{1 - \omega_a g_a^2} \]

As for their cloudy counterparts, \( R_{cI} \) and \( T_{cI} \) must account for the multiple reflections due to the layers underneath

\[
R_{cI} = R(\mu) + R(\mu) T(\mu) / (1 - R^* R_\infty) \tag{3.30}
\]

\[
T_{cI} = T(\mu) / (1 - R^* R_\infty)
\]

with \( R^* = R (1/r) \)
\[
T^* = T (1/r)
\]

and \( R_\infty \) is the reflectance of the underlying medium \( (R_\infty = R_t (j-1)) \) and \( r \) is the diffusivity factor.

Since interactions between molecular absorption and Rayleigh and aerosol scattering are negligible, the radiative fluxes in a clear-sky atmosphere are simply those calculated from (3.12) and (3.30) attenuated by the gaseous transmissions (3.10).

### 3.3 Multiple reflections between layers

To deal properly with the multiple reflections between the surface and the cloud layers, it should be necessary to separate the contribution of each individual reflecting surface to the layer reflectances and transmittances inasmuch as each such surface gives rise to a particular distribution of absorber amount. In case of an atmosphere including \( N \) cloud layers, the reflected light above the highest cloud consists of photons directly reflected by the highest cloud without interaction with the underlying atmosphere, and of photons that have passed through this cloud layer and undergone at least one reflection on the underlying atmosphere. In fact, (3.6) should be written

\[
F = \sum_{i=0}^{N} F_{cI} \int_{0}^{\infty} p_1(U) t_{\Delta \nu}(U) \, d\nu \tag{3.31}
\]
where \( F_{cl} \) and \( p_j(U) \) are the conservative fluxes and the distributions of absorber amount corresponding to the different reflecting surfaces.

Fouquart and Bonnel (1980) have shown that a very good approximation to this problem is obtained by evaluating the reflectance and transmittance of each layer (using (3.24) and (3.30)) assuming successively a non-reflecting underlying medium \( (R_\perp = 0) \), then a reflecting underlying medium \( (R_\perp \neq 0) \). First calculations provide the contribution to reflectance and transmittance of those photons interacting only with the layer into consideration, whereas the second ones give the contribution of the photons with interactions also outside the layer itself.

From these two sets of layer reflectances and transmittances \( (R_{t0} \ , \ T_{b0}) \) and \( (R_{t\perp} \ , \ T_{b\perp}) \) respectively, effective absorber amounts to be applied to computing the transmission functions for upward and downward fluxes are then derived using (3.8) and starting from the surface and working the formulas upward

\[
\begin{align*}
U_{e0}^- &= \ln \left( \frac{T_{b0}}{T_{bc}} \right) / k_e \\
U_{e\perp}^- &= \ln \left( \frac{T_{b\perp}}{T_{bc}} \right) / k_e \\
U_{e0}^+ &= \ln \left( \frac{R_{t0}}{R_{tc}} \right) / k_e \\
U_{e\perp}^+ &= \ln \left( \frac{R_{t\perp}}{R_{tc}} \right) / k_e
\end{align*}
\]

(3.32)

where \( R_{tc} \) and \( T_{bc} \) are the layer reflectance and transmittance corresponding to a conservative scattering medium.

Finally the upward and downward fluxes are obtained as

\[
\begin{align*}
F^+(j) &= F_0 \left[ R_{t0} \ t_{\Delta \nu} (U_{e0}^+) + (R_{t\perp} - R_{t0}) \ t_{\Delta \nu} (U_{e\perp}^+) \right] \quad (3.33a) \\
F^-(j) &= F_0 \left[ T_{b0} \ t_{\Delta \nu} (U_{e0}^-) + (T_{b\perp} - T_{b0}) \ t_{\Delta \nu} (U_{e\perp}^-) \right] \quad (3.33b)
\end{align*}
\]
3.4 Cloud shortwave optical properties

As seen in section 3.2.1, the cloud radiative properties depend on three different parameters: the optical thickness \( \delta_c \), the asymmetry factor \( g_c \), and the single scattering albedo \( \omega_c \).

\( \delta_c \) is related to the cloud liquid water amount \( u_{LWP} \) by

\[
\delta_c = \frac{3 \ u_{LWP}}{2 \ r_e}
\]  

(3.34)

where \( r_e \) is the mean effective radius of the size distribution of the cloud droplets. Presently \( r_e \) is fixed to 15 \( \mu \text{m} \), but this radius may vary with height from 5 \( \mu \text{m} \) in the planetary boundary layer to 40 \( \mu \text{m} \) at 100 hPa, in an empirical attempt at dealing with the variation of cloud type with height. Smaller water droplets are observed in low-level stratiform clouds whereas larger particles are found in cumuliform and cirriform clouds.

In the two spectral intervals of the shortwave radiation scheme, \( g_c \) is fixed to 0.865 and 0.910, respectively, and \( \omega_c \) is given as a function of \( \delta_c \) following Fouquart (1987)

\[
\omega_{c1} = 0.9999 - 5 \times 10^{-4} \exp(-0.5 \delta_c) \\
\omega_{c2} = 0.9988 - 2.5 \times 10^{-3} \exp(-0.05 \delta_c)
\]  

(3.35)

These cloud shortwave radiative parameters have been fitted to in situ measurements of stratocumulus clouds (Bonnel et al., 1983).
